# Foreword

Airfoils for wind turbines have been selected by comparing data from different wind tunnels, tested under different conditions, making it difficult to make accurate comparisons. Most wind tunnel data sets do not contain airfoil performance in stall commonly experienced by turbines operating in the field. Wind turbines commonly experience extreme roughness for which there is very little data. Finally recent tests have shown that dynamic stall is a common occurrence for most wind turbines operating in yawed, stall or turbulent conditions. Very little dynamic stall data exists for the airfoils of interest to wind turbine designer. In summary, very little airfoil performance data exists which is appropriate for wind turbine design.

Recognizing the need for a wind turbine airfoil performance data base the National Renewable Energy Laboratory (NREL), funded by the US Department of Energy, awarded a contract to Ohio State University (OSU) to conduct a wind tunnel test program. Under this program OSU has tested a series of popular wind turbine airfoils. A standard test matrix has been developed to assure that each airfoil was tested under the same conditions. The test matrix was developed in partnership with industry and is intended to include all of the operating conditions experienced by wind turbines. These conditions include airfoil performance at high angles of attack, rough leading edge (bug simulation), steady and unsteady angles of attack.

Special care has been taken to report as much of the test conditions and raw as practical so that designers can make their own comparisons and focus on details of the data relevant to their design goals. Some of the airfoil coordinates are proprietary to NREL or an industry partner. To protect the information which defines the exact shape of the airfoil the coordinates have not been included in the report. Instructions on how to obtain these coordinates may be obtained by contacting C.P. (Sandy) Butterfield at NREL.

# Abstract

Wind turbines in the field can be subjected to many and varying wind conditions, including high winds with the rotor locked or with yaw excursions. In some cases, the rotor blades may be subjected to unusually large angles of attack that possibly result in unexpected loads and deflections. To better understand loadings at unusual angles of attack, a wind tunnel test was performed.

An 18-inch constant-chord model of the LS(1)-0417MOD airfoil section was tested under two dimensional steady state conditions in the Ohio State University Aeronautical and Astronautical Research Laboratory 7x10 Subsonic Wind Tunnel. The objective of these tests was to document section lift and moment characteristics under various model and air flow conditions. Surface pressure data was acquired at  $-60^\circ$  through  $+230^\circ$  geometric angles of attack, at a nominal 1 million Reynolds number. Cases with and without leading edge grit roughness were investigated. The leading edge roughness was used to simulate blade conditions encountered on wind turbines in the field. Additionally, surface pressure data were acquired for Reynolds numbers of 1.5 and 2.0 million, with and without leading edge grit roughness; the angle of attack was limited to a  $-20^\circ$  to  $40^\circ$  range.

In general, results showed lift curve slope sensitivities to Reynolds number and roughness. The maximum lift coefficient was reduced as much as 29% by leading edge roughness. Moment coefficient showed little sensitivity to roughness beyond  $50^\circ$  angle of attack, but the expected decambering effect of a thicker boundary layer with roughness did show at lower angles.

Tests also were conducted with vortex generators located at the 30% chord location on the upper surface only, at 1 and 1.5 million Reynolds numbers, with and without leading edge grit roughness. In general, with leading edge grit roughness applied, the vortex generators restored 85 percent of the baseline level of maximum lift coefficient but with a more sudden stall break and at a higher angle of attack than the baseline.

The staff of the Ohio State University Aeronautical and Astronautical Research Laboratory appreciate the contributions made by personnel from both organizations.

# Introduction

Wind turbines in the field can be subjected to many and varying wind conditions, including high winds with the rotor locked or with yaw excursions. In some cases the rotor blades may be subjected to unusually large angles of attack that possibly result in unexpected loads and deflections. To better understand loadings at unusual angles of attack, a wind tunnel test was performed. An 18-inch constant-chord model of the LS(1)-0417MOD airfoil section was tested under two-dimensional, steady state conditions in the Ohio State University Aeronautical and Astronautical Research Laboratory (OSU/AARL) 7x10 Subsonic Wind Tunnel (7x10). The objective of these tests was to document section lift and moment characteristics under various model and air flow conditions. These included a normal angle of attack range of  $-20^\circ$  to  $+40^\circ$ , an extended angle of attack range of  $-60^\circ$  to  $+230^\circ$ , applications of leading edge grit roughness (LEGR), and use of vortex generators (VGs), all at chord Reynolds numbers as high as possible for the particular model configuration. To realistically satisfy these conditions the 7x10 offered a tunnel-height-to-model-chord ratio of 6.7, suggesting low interference effects even at the relatively high lift and drag conditions expected during the test. Significantly, it also provided chord Reynolds numbers up to 2.0 million.

Knowing the LS(1)-0417MOD model would later be run in the OSU/AARL 3x5 Subsonic Wind Tunnel (3x5), the present test setup and methods were kept as similar as possible to those for the 3x5. This will allow a direct comparison of data obtained in the two wind tunnels. Consequently, most of the data acquisition equipment was moved from the 3x5 to the 7x10. Minor changes were made to the system in order to adapt the equipment to the larger facility. Also, so that the LS(1)-0417MOD model could be used in both tunnels, it was specially designed to include a central 3-foot span sensing section with removable, contoured, spanwise extensions.

A "standard" grit pattern was applied in all LEGR cases. The grit pattern was developed by U.S. Windpower, OSU/AARL, and the University of Texas, Permian Basin. The VGs were provided to OSU/AARL by U.S. Windpower. Detailed discussion of the grit pattern and VGs can be found in the Section, Model Details.

Reynolds numbers of 1, 1.5, and 2 million were tested for normal angle of attack range cases ( $-20^\circ$  to  $+40^\circ$ ). At 1 million Reynolds number, the model was additionally swept through the extended angle of attack range. The model buffeted at higher dynamic pressures, thus precluding higher Reynolds number data for extended angle of attack range. However, both clean and LEGR data were taken for all useable tunnel conditions. Finally, VG effects were evaluated over the normal angle of attack range, for Reynolds numbers of 1 and 1.5 million, and for clean and LEGR cases. The VGs were tested at the 30% chord upper surface station only; any attempt at higher Reynolds numbers with VGs consistently result in VGs separating from the model. Scheduling constraints precluded any significant effort to alleviate the VG attachment problem.

# Test Facility

Tests described here were performed in the OSU/AARL 7x10 subsonic wind tunnel. A schematic of the tunnel is shown in figure 1. There are two test sections in this tunnel: a 7-foot by 10-foot section in which these tests were conducted, and a 16-foot by 14-foot section in which very low speed and high angle of attack testing is performed with large models. The wind tunnel is a closed-circuit, single-return, continuous-flow system. A velocity range of 35 to 180 knots is developed in the 7x10 test section by a six-blade, fixed-pitch, 20-foot diameter fan directly driven by a 2000-horsepower, variable-speed motor. The tunnel's steel outer shell is water spray cooled to control internal air temperature. Its test section floor contains a rotating table which allows adjustment of the model angle of attack through a 290° range about a vertical axis. A large, long traverse, wake survey probe was not available; consequently, none was installed in the test section.

Figure 1. OSU/AARL 7x10 Subsonic Wind Tunnel

## Model Details

An 18-inch constant-chord LS(1)-0417MOD airfoil model was designed by OSU/AARL personnel and manufactured by others. Figure 2 shows the airfoil section; the section's measured coordinates are given in Appendix A. The model was made of a carbon composite skin over a foam core. The main load bearing member is a 1½-inch diameter steel tube that passes through the foam core at the airfoil quarter chord station. Steel and composite ribs and end plates transfer loads from the composite skin to the steel tube. The final surface was hand worked using templates to attain given coordinates within a tolerance of  $\pm 0.01$  inches.

LS(1)-0417MOD

Figure 2. LS(1)-0417MOD Airfoil Section

Since the model also had to be used in the 3x5 subsonic wind tunnel for additional tests, it was designed with a 3-foot span main sensing section and 2-foot extension panels for each end, shown in figure 3. The extensions, used for 7x10 tunnel testing, were fabricated with the same contour as the main section. They slide over the steel tube and fasten to the endplates of the main section. Other minor model features were included, such as an extension to the model support tube and an adaptation of the support tube end to accommodate the different angle of attack potentiometer mountings in each facility.

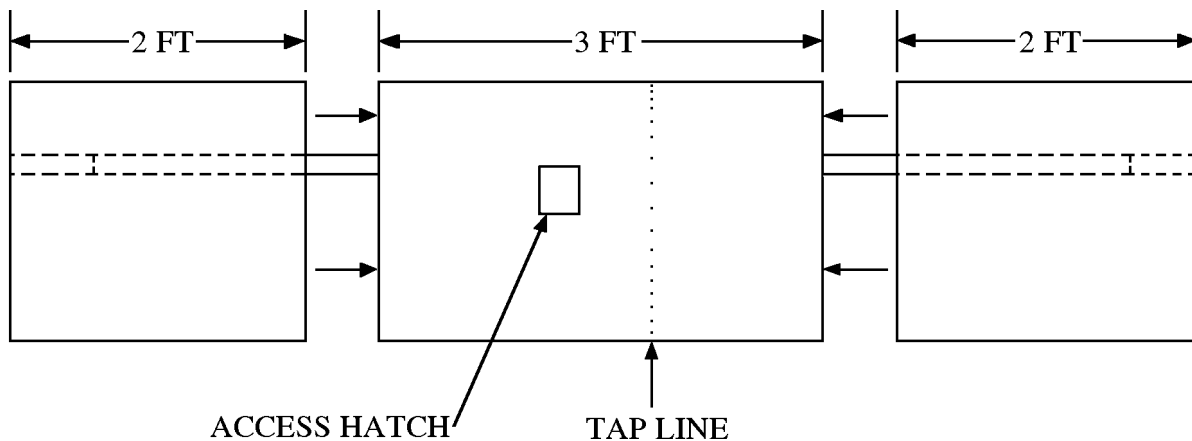

Figure 3. Model Design

To minimize pressure response times, the lengths of surface pressure tap leadout lines were made as short as possible. Although response time was not particularly important for the present test, it was important for the unsteady testing to be done later in the 3x5 wind tunnel. Therefore, a compartment was built into the model to hold the pressure scanning modules. This compartment can be accessed through a panel door fitted flush with the model contour on the lower (pressure) surface.

For test cases involving roughness, to have a standard, repeatable pattern with grit as roughness elements was desired. Prior to these tests, grit was lightly blown into a thin layer of spray adhesive or a tape adhesive to obtain a roughened surface on models. A different method was developed and used here. OSU/AARL and U.S. Windpower personnel jointly developed a roughness pattern using a molded insect pattern taken from a wind turbine in the field by personnel at the University of Texas, Permian Basin.

The resultant particle density was 32 particles per square inch in the middle of the pattern, and thinning to 8 particles per square inch at the edge of the pattern. Figure 4 shows the pattern template produced by U.S. Windpower from these specifications. The pattern was repeatedly cut into a steel sheet 4-inches wide and 3-feet long with holes just large enough for one piece of grit. Based on average particle size from the field specimen, standard #40 lapidary grit was chosen for the roughness elements, giving  $k/c=0.0019$  for an 18 inch chord model.

**Figure 4. Roughness Pattern**

To use the template, 4-inch wide double-tack tape was stuck to one side of the template and grit was poured and brushed from the opposite side. The tape was then removed from the template and transferred to the model. This scheme allowed the same roughness pattern to be replicated for any test.

VGs were applied to the model for some data points. U.S. Windpower provided the VGs with the geometry shown in figure 5. The VGs were pairs of right isosceles triangular shapes set on their longest sides at  $30^\circ$  included angle to each other and  $15^\circ$  to the chord line. The pairs were repeated every 1.61 inches in the spanwise direction. This VG configuration was fabricated in 1.53-inch wide injection-molded plastic strips with a 0.036-inch base-plate thickness. For ease of installation and to minimize damage to the model surface, these strips were fastened at the 30% chord upper surface station using rubber cement between the VG base-plate and model, and thin tape (0.003-inch thick) over the base plate leading and trailing edges.

# Test Equipment and Procedures

## Data Acquisition

Data was acquired and processed from up to 60 surface pressure taps, three individual tunnel pressure transducers, and an angle of attack potentiometer. The data acquisition system included an IBM PC compatible 80386-based computer connected to a Pressure Systems Incorporated (PSI) data scanning system. The PSI system included a 780B Data Acquisition and Control Unit (DACU), 780B Pressure Calibration Unit (PCU), 81-IFC scanning module interface, two ESP-32 5-psid range pressure scanning modules (ESPs), and a 30-channel Remotely Addressed Millivolt Module (RAMM-30). Figure 6 shows the data acquisition system schematic.

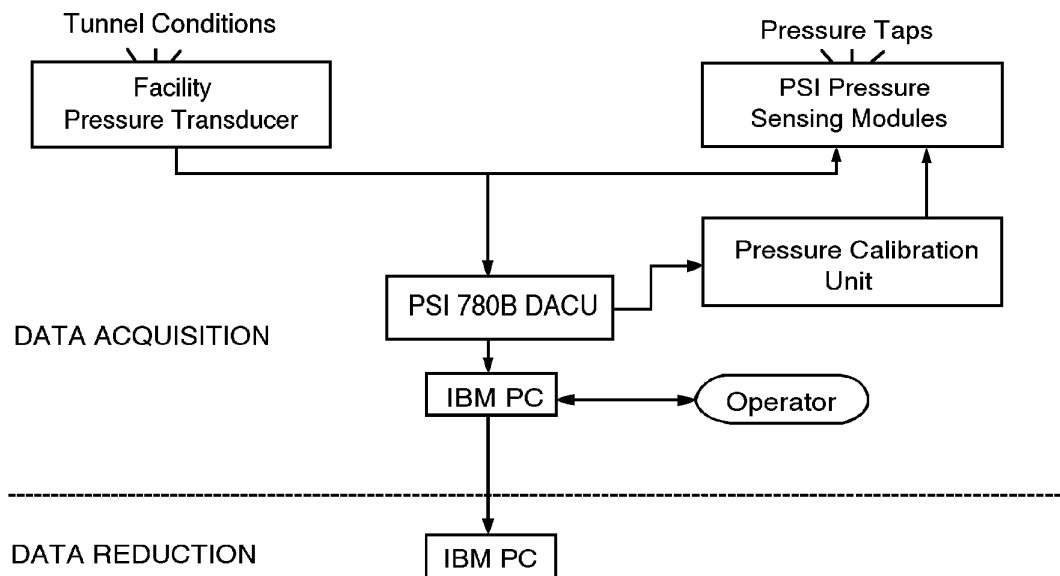

Figure 6. Data Acquisition Schematic

Three individual pressure transducers read tunnel total pressure, tunnel east static pressure, and tunnel west static pressure. Before the test began, these transducers were bench calibrated using a water manometer to determine their sensitivities and offsets. Related values were entered into the data acquisition and reduction program so the transducers could be shunt-resistor calibrated before each series of wind tunnel runs.

The angle of attack potentiometer was a linear rotary potentiometer and was regularly calibrated during the tunnel pressure transducers shunt calibration. The angle of attack calibration was accomplished by taking voltage readings at known values of set angle of attack. This calibration method gave angle of attack readings within  $\pm 0.25^\circ$  of actual over the entire angle range.

Two ESPs were calibrated simultaneously using the DACU and PCU. At operator request, the DACU commanded the PCU to apply known regulated pressures to the ESPs and read the output voltages from each integrated pressure sensor. From these values, the DACU calculated the calibration coefficients and stored them internally until the coefficients were requested by the controlling computer. This calibration was done

several times during a run set because the ESPs were installed inside the model and their outputs tended to drift with temperature changes during a test sequence. Frequent online calibrations minimized the effect.

Finally, at operator request, pressure measurements from the airfoil surface taps and all other channels of information were acquired and stored by the DACU and subsequently passed to the controlling computer for final processing.

## Data Reduction

The data reduction routine was incorporated as a section of the data acquisition program. This combined data acquisition and reduction routines allowed data to be reduced online during a test. By quickly reducing selected runs, integrity checks could be made to insure the equipment was working properly and to enable timely decisions about the test matrix.

The ambient pressure and tunnel air temperature were manually input into the computer and were updated regularly. These values, as well as the measurements from the tunnel pressure transducers, were used to calculate tunnel airspeed. As a continuous check of readings, both the tunnel individual pressure transducers and the ESPs read the tunnel total and static pressures.

A typical data point was derived by acquiring twenty data scans of all channels over a 1-second window at each angle of attack and tunnel condition. The reduction portion of the program processed each data scan to coefficient forms  $C_p$ ,  $C_l$ ,  $C_{m/4}$ , and  $C_{dp}$  using the measured surface pressure voltages, calibration coefficients, tap locations and wind tunnel conditions. All scan sets for a given condition were then ensemble averaged to provide one set. All data were saved in electronic form. The data were not corrected for any tunnel wall effects, etc.

## Test Matrix

The test was designed to allow an extended angle of attack range of  $-60^\circ$  to  $230^\circ$  and Reynolds numbers of 1, 1.5, and 2 million with and without LEGR. The tabular data in Appendix B contains the actual Reynolds number for each angle of attack. The angle of attack increment was 4-degrees when  $\alpha < -20^\circ$  or  $\alpha > 40^\circ$ , 2-degrees when  $-20^\circ < \alpha < 10^\circ$  or  $20^\circ < \alpha < 40^\circ$ , and 1-degree when  $10^\circ < \alpha < 20^\circ$ . All test speeds and angles of attack were set for model clean and LEGR conditions.

For some cases, VGs were mounted at the 30% chord position on the model's upper surface only. The VG strips were provided by U.S. Windpower and were the exact type used on wind turbines in the field. Test conditions while the VGs were applied included clean and LEGR data at 1 and 1.5 million Reynolds numbers over an angle of attack range of  $-20^\circ$  to  $40^\circ$ .

Unexpected complications during testing forced adjustments to this desired test matrix. Those complications and their effects are elaborated in the next section, Results and Discussion.

## Results and Discussion

The LS(1)-0417MOD airfoil model was tested at three Reynolds numbers in the 7x10. Unfortunately, due to less than expected model rigidity, the model flexed and fluttered when near perpendicular to the flow at the higher test airspeeds. The tunnel airspeed was reduced for those conditions to reduce dynamic effects and to preserve the model's structural integrity. Consequently, the Reynolds number was not constant for the entire extended angle of attack sweeps and only the nominal 1 million Reynolds number condition was obtained. The Reynolds number was as low as 0.6 million during the nominal 1 million Reynolds number extended angle of attack cases. Also, no wake survey probe was available for the test; only pressure drag from surface pressure integrations is presented.

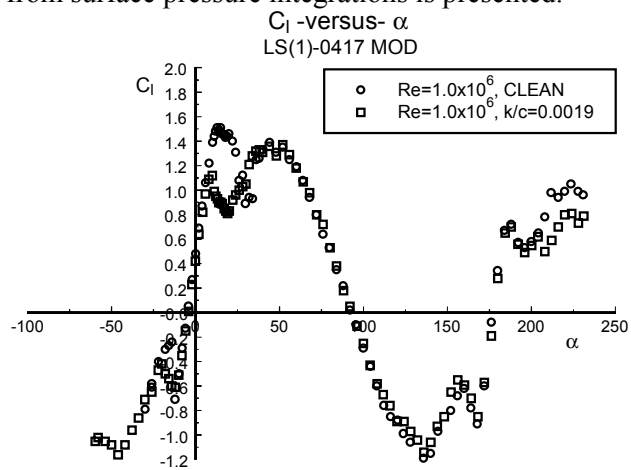

Figure 7.  $C_l$  vs  $\alpha$  Extended Range

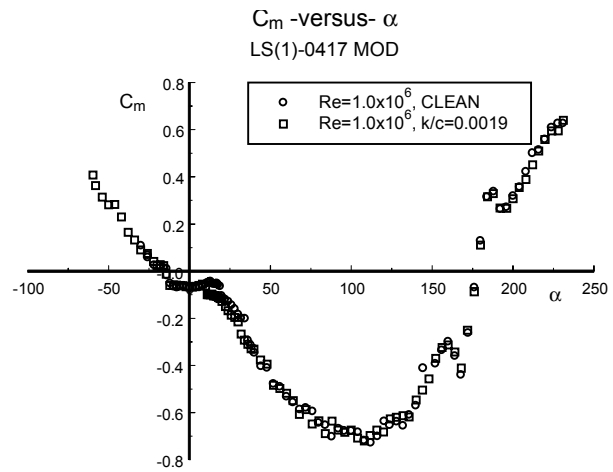

Figure 8.  $C_{m_{1/4}}$  vs  $\alpha$  Extended Range

Figure 7 shows the lift coefficient versus angle of attack for the extended angle of attack sweeps, for the model clean and with LEGR at 1 million Reynolds Number. Increases in lift coefficient occurred when the model was in its post stall region for both positive and negative angles of attack; the maximum lift coefficient occurred just before positive stall and is 1.51. Correspondingly, for the LEGR data, the maximum lift coefficient prior to stall is 1.12 and occurs at a slightly lower angle of attack in comparison with the clean case. The overall maximum lift of the LEGR case does not occur before stall but beyond it near  $45^\circ$  angle of attack. This can be observed in figure 7. Similar magnitudes of  $C_l = 1.35$  also are apparent in the large angle of attack clean cases.

The quarter chord pitching moment results are shown in figure 8 for the Reynolds number of 1 million. The pitching moment is most negative when the airfoil is at high angles of attack, near  $110^\circ$ . This observation is consistent for both clean and LEGR cases. The pressure drag is shown in figure 9. The highest pressure drag occurs when the model is near  $90^\circ$  angle of attack. There is some scatter in the data at such conditions, caused by the severely detached, unstable flow on the leeward side of the model.

A number of test runs were made for nominal angles of attack from  $-20^\circ$  to  $+40^\circ$ . For some of the cases, there is no data shown for the highest angles of attack; the data was discounted as unreliable because the model was buffeting. Figure 10 and 11 show lift coefficient for all the test Reynolds numbers, for the model clean and with LEGR. The maximum positive lift coefficient for the clean cases is about 1.63 and the LEGR data have a  $C_{l_{max}}$  about 1.2. For the clean cases, the airfoil stalls more abruptly with higher Reynolds

numbers. Also note that for the 1 million Reynolds number case, the model with LEGR seems to stall more abruptly than the clean airfoil. The average lift curve slope for these data is about 0.1.

Figure 9.  $C_{dp}$  vs  $\alpha$  Extended Range

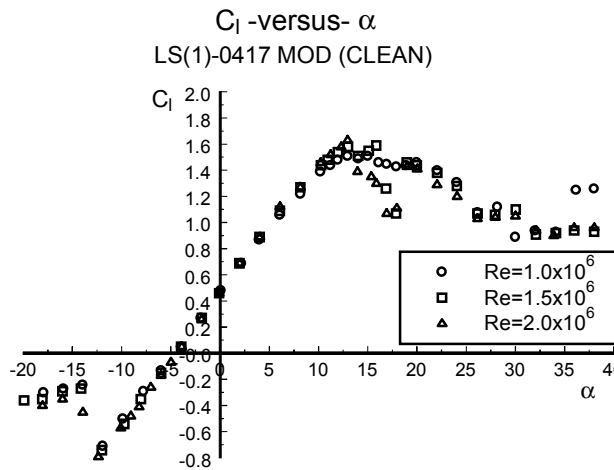

Figure 10.  $C_l$  vs  $\alpha$  Clean

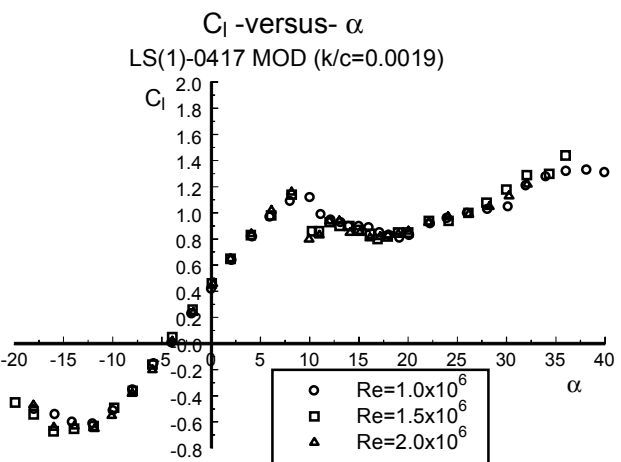

Figure 11.  $C_l$  vs  $\alpha$  LEGR,  $k/c=0.0019$

Figure 12 shows the pitching moment about the quarter chord for the clean cases; figure 13 shows the LEGR cases. The LEGR data show a more positive pitching moment near  $0^\circ$  angle of attack. However, beyond stall, the pitching moment magnitude increases faster for the model with LEGR than for the clean model. The  $C_{mo}$  about the quarter chord for the clean case is  $-0.080$  and  $-0.067$  for the LEGR case.

VGs were fitted to the model at the 30% chord location, upper surface (suction side) only. The results from these cases are shown in figure 14 for lift coefficient, and in figure 15, for pitching moment coefficient. The maximum lift coefficient for the clean case with VGs is near 1.88 and near 1.41 for the LEGR case. This is a 25% reduction in maximum lift when the airfoil has leading edge roughness. The stall of this airfoil is more abrupt when the VGs are applied, and occurs at a slightly higher angle of attack than without VGs. The pitching moment shows slightly different characteristics with the VGs than without. Pre-stall pitching moment magnitude slightly increases with increased angle of attack with VGs applied, but slightly decreases without VGs. The pitching moment is affected more near stall without VGs than when the VGs are applied. Pressure drag for the VGs cases but is included only for completeness sake in figure 16. This form of drag

coefficient is inherently inaccurate because it does not include friction drag and should only be used for comparisons within the present data sets.

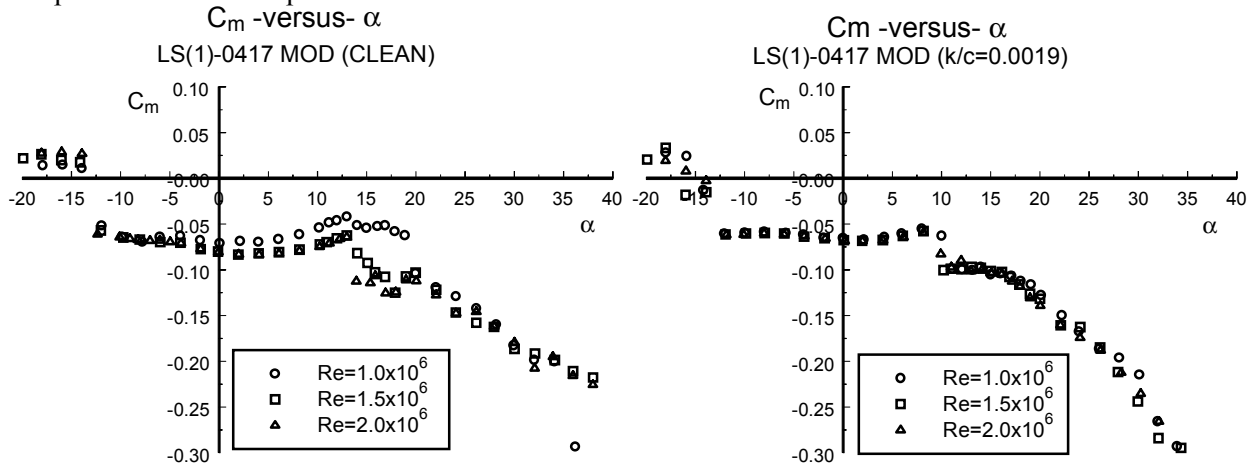

Figure 12.  $C_{m\frac{1}{4}}$  vs  $\alpha$  Clean

Figure 13.  $C_{m\frac{1}{4}}$  vs  $\alpha$  LEGR,  $k/c=0.0019$

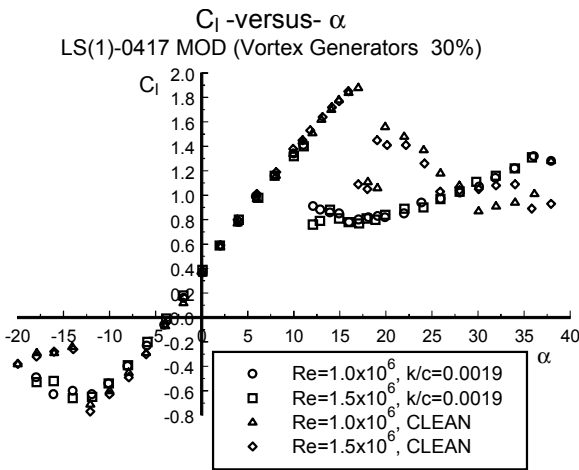

Figure 14.  $C_1$  vs  $\alpha$  Vortex Generators

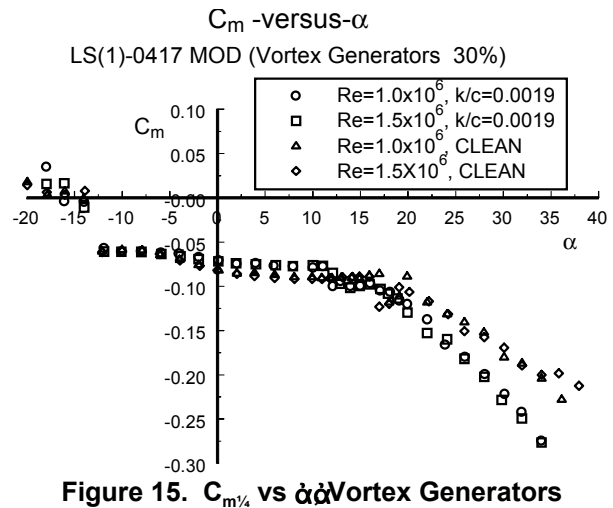

Figure 15.  $C_{m\frac{1}{4}}$  vs  $\alpha$  Vortex Generators

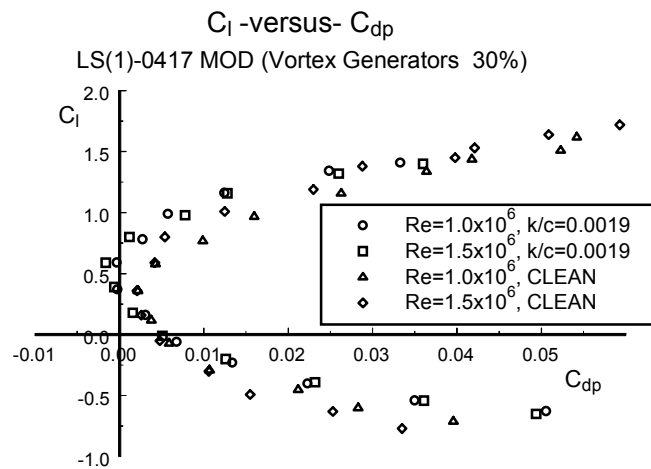

Figure 16. Drag Polar, Vortex Generators,  $C_1$  vs  $C_{dp}$

All the pressure distributions shown are for a Reynolds number of 1 million and show cases of clean, LEGR, and VGs with and without LEGR. Figure 17 shows the pressure distributions for  $0^\circ$  angle of attack. A trend toward reduced pressure magnitudes with LEGR can be observed. At angles of attack near stall, the trending is more apparent. For example, figure 18 shows pressure distributions for a  $15^\circ$  angle of attack. The data show the model has upper surface flow separation near the 20% chord station for the LEGR case. It further shows that the VGs increase the pressure magnitudes for both the clean and LEGR cases. Also, the VGs cause the separation point to move aft.

Figure 17.  $C_p$  vs  $x/c$ ,  $\alpha=0^\circ$

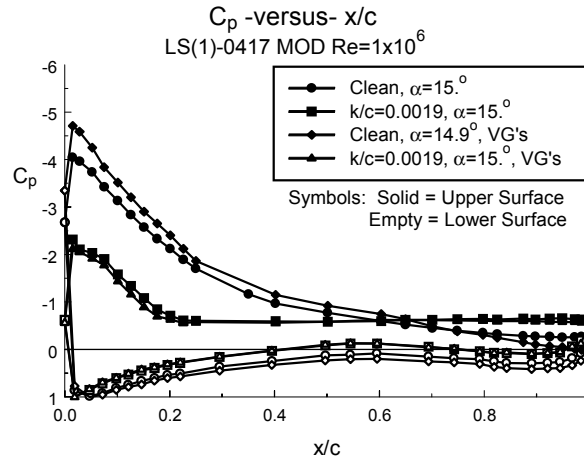

Figure 18.  $C_p$  vs  $x/c$ ,  $\alpha=15^\circ$

Figure 19 shows pressure data from the model at an angle of attack of  $184^\circ$  including clean and LEGR pressure distributions. The distributions are almost identical over the airfoil. This shows the roughness does not affect the airflow since it is located, for this unusual case, downstream of the trailing edge.

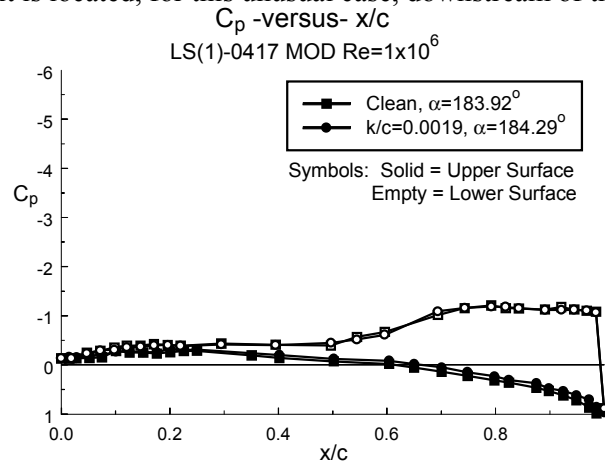

Figure 19.  $C_p$  vs  $x/c$ ,  $\alpha=184^\circ$

The final tests conducted on this wind tunnel model in the 7x10 were to repeat clean conditions at Reynolds numbers of 1 million and 1.5 million for a smaller angle of attack calibration range. In this case, the potentiometer measuring angle of attack was calibrated over a smaller range of  $-30^\circ$  to  $30^\circ$  which made the angle of attack reading more sensitive than those for the other tests. The aerodynamic coefficients for this data are tabulated in Appendix B.

The pressure distributions and coefficient data for other test conditions are in Appendix B.

## Summary

A LS(1)-0417MOD model was installed in the OSU/AARL 7x10 subsonic wind tunnel and tested at three Reynolds numbers and with model clean, roughened, and with VGs. Table 1 is a summary of the aerodynamic coefficient data for the LS(1)-0417MOD.

**Table 1. LS(1)-0417MOD Aerodynamic Parameters Summary**

CASE	Re num	$C_{l_{max}}$	$dC_l/d\dot{\alpha}\dot{\alpha}$	$C_{m_0}$
Clean	$1.0 \times 10^6$	1.51	0.099	-0.071
Clean	$1.5 \times 10^6$	1.58	0.103	-0.080
Clean	$2.0 \times 10^6$	1.63	0.107	-0.080
k/c=0.0019	$1.0 \times 10^6$	1.12	0.099	-0.065
k/c=0.0019	$1.5 \times 10^6$	1.14	0.098	-0.067
k/c=0.0019	$2.0 \times 10^6$	1.16	0.102	-0.068
Clean VG's	$1.0 \times 10^6$	1.88	0.105	-0.082
Clean VG's	$1.5 \times 10^6$	1.85	0.107	-0.082
k/c=0.0019 VG's	$1.0 \times 10^6$	1.41	0.105	-0.070
k/c=0.0019 VG's	$1.5 \times 10^6$	1.40	0.099	-0.072

For the clean LS(1)-0417MOD model, Reynolds number changes from 1 to 2 million did not a significant affect the maximum positive lift or the pitching moment at zero degrees angle of attack. However, the addition of leading edge grit roughness to the model reduced the maximum lift coefficient by 28% and caused a 16% change in the pitching moment at zero degrees angle of attack. Also, the lift curve slope showed slight increases with Reynolds number. Adding VGs on the model's upper surface at the 30% chord station caused the maximum lift coefficient to increase by 25% in the clean cases and by about 26% for the roughened cases. The VGs apparently energized the boundary layer sufficiently to increase the lift curve slope and to delay stall to a higher angle of attack and, consequently, a higher maximum lift coefficient. However, the positive stall with VG's was more abrupt than the stall without VG's.
